

ANALYSIS AND MAPPING OF RNA POLYMERASE II  
TERMINATION FACTORS

by

Paul Schaughency

A dissertation submitted to Johns Hopkins University in conformity with the  
requirements for the degree of Doctor of Philosophy.

October, 2014

## ABSTRACT

Termination of transcription is an important, but poorly understood, cellular process. RNA polymerase II (Pol II) terminates coding transcripts and non-coding transcripts (ncRNAs) through two distinct mechanisms in yeast. In the non-poly(A) dependent pathway, Nrd1 and Nab3 bind to their recognition sites on the nascent RNA of ncRNAs to cause termination. This is done through an unknown mechanism, but is known to involve the RNA-DNA helicase Sen1. In our first study, we have mapped Pol II distribution before and after depletion of different termination factors. This was done, by depleting each factor from the nucleus and then using PAR-CLIP to assess the position of Pol II. Nrd1 depletion leads to widespread runaway transcription at non-poly(A) terminators. In contrast, depletion of Sen1 or Ysh1, an endonuclease involved in the poly(A) dependent pathway, does not lead to elevated readthrough transcription. These differences allowed us to map all the non-poly(A) termination regions throughout the yeast genome. Our second study follows the human homolog of Nrd1, RBM16. RBM16 shares a common protein domain architecture and a conserved CTD interacting domain with Nrd1. Although it is unclear whether there is a similar non-poly(A) termination pathway in human cells, we show that there are at least similarities between the classes of RNAs that are bound to both Nrd1 and RBM16. The final study focuses on the unique methodologies used to analyze PAR-CLIP datasets. It describes computer programs and bioinformatic pipelines written to provide answers to basic questions based on PAR-CLIP data. The functions created to answer these questions could be applicable to a wide variety of data. The studies presented here provide a foundation so that fundamental mechanisms of termination can be elucidated.

Thesis Advisor: Jeffry Corden, PhD.

Thesis Reader: Randall Reed, PhD.

## **PREFACE**

I would like to thank my thesis advisor Jeffry Corden. Without his support, none of what I write below would have happened. I would also like to thank the past and present members of the Corden and Cormack labs, my thesis committee members (Randall Reed, Jon Lorsch, Rachel Green, and Brendan Cormack), my family, my friends, and the BCMB administration staff for encouragement and support during these past years.

Years later, as I look back upon that fresh recruit into the BCMB program, I hardly recognize that person. I am thankful I have had the opportunity to learned many uncountable things over these past years. In truth, though, I could not have done it without the support of many people. I know I have left someone out in this brief preface, but be assured that I do appreciated all the help people have given me over the years here at Hopkins. As I end this chapter in my life, I realized I now have a solid foundation to build a career in science.

Paul Schaughency

## INTRODUCTION

RNA Polymerase II (Pol II) is responsible for all messenger RNA (mRNA) and some non-coding RNA (ncRNA) transcription in eukaryotes. The proteins involved, and the time at which they bind, can define the cycle of transcription. Recruitment and initiation of Pol II on the DNA template is the first step. This is closely followed by elongation of the nascent RNA and, eventual termination of the transcript. The cycle of transcription has been extensively studied and reviewed (Barrero and Malik, 2013; Shandilya and Roberts, 2012; Svetlov and Nudler, 2013). Proper termination of Pol II is essential to maintaining a pool of free enzyme and to prevent Pol II from interfering with downstream genes (Kuehner et al., 2011; Mischo and Proudfoot, 2013). This could happen through collision with oncoming Pol II or dislodging transcription factors on the downstream DNA template (Castelnuovo et al., 2013; Cloutier et al., 2013; Shearwin et al., 2005). In yeast, Pol II termination has been shown to provide a regulatory purpose through premature termination of certain genes (Creamer, 2011; Kuehner and Brow, 2008; Thiebaut et al., 2008).

The C-terminal domain (CTD) of Pol II contains a heptad repeat that acts a scaffold for protein recruitment during the transcriptional cycle (Buratowski, 2009). The consensus sequence (YSPTSPS) of this CTD is conserved from yeast to mammals. Each repeat of the CTD is modified during the transcription cycle to reflect the state of Pol II transcription (Chapman et al., 2007; Zhang and Corden, 1991). This “CTD Code” is a set of phosphorylation and other post-translational modifications that alter which sets of proteins are bound to the scaffold and, ultimately, influence Pol II transcription

(Buratowski, 2009; Carroll et al., 2007; Komarnitsky et al., 2000; Nedea et al., 2003).

The most well understood part of the CTD code is phosphorylation of serine residues within the heptad repeat. After initiation of Pol II on the DNA template and early elongation, there is an abundance of phosphorylation on the fifth serine (Ser5) in the tandem repeats. At the 3' end of the template, there is more phosphorylation of the second serine (Ser2). These patterns allow the CTD to be a dynamic scaffold for many different co-transcriptional machines (Corden, 2013; Hsin and Manley, 2012; Napolitano et al., 2014).

Pol II pervasively transcribes many ncRNAs throughout the yeast genome (Berretta and Morillon, 2009; Jacquier, 2009; Jensen et al., 2013). These ncRNAs can be categorized into three subclasses: Cryptic Unstable Transcripts (CUTs) that are readily degraded by the nuclear exosome (Arigo et al., 2006; Davis and Ares, 2006; Gudipati et al., 2012; Neil et al., 2009; Thiebaut et al., 2006; Wyers et al., 2005), Stable uncharacterized transcripts (SUTs) that do not rely on the nuclear exosome to be observed (Xu et al., 2009) and Xrn1-dependent transcripts (XUTs) that are only found in the absence of the nuclease Xrn1 (van Dijk et al., 2011).

In yeast, termination of mRNAs and some SUTs happen through the cleavage and polyadenylation (pA) machinery. Loosely conserved sequences at the 3' end of the transcript act as signal for binding of the CF1 complex, which leads to the recruitment of the pA machinery and termination of the transcript (Kuehner et al., 2011; Mischo and Proudfoot, 2013). The mechanism of this action has yet to be elucidated. snoRNA and other ncRNA termination happens through the Nrd1-Nab3-Sen1 (NNS) pathway. Unlike pA-mediated termination, the NNS pathway binds early in transcription when Ser5

phosphorylation of the CTD is high (Chinchilla et al., 2012). Similarly to pA-termination, Nrd1 and Nab3 recognized RNA sequences elements downstream of certain ncRNAs (Carroll et al., 2007; Carroll et al., 2004; Creamer, 2011; Porrua et al., 2012; Steinmetz et al., 2001; Steinmetz et al., 2006; Wlotzka et al., 2011). This leads to recruitment of the DNA/RNA helicase Sen1 as well as the nuclear exosome (Conrad et al., 2000; Steinmetz and Brow, 1996, 1998; Steinmetz et al., 2001; Ursic et al., 2004). How these factors work together to direct termination and turnover is not well understood.

Two possible mechanisms for transcriptional termination have been proposed. In the first, the exposed uncapped 5' end of the nascent transcript, after cleavage from the poly-A site, recruits a 5' → 3' exonuclease. In yeast, this protein is Rat1 while in metazoans the protein is Xrn2 (Kim et al., 2004; West et al., 2004). In this model, Pol II is already paused downstream of the poly-A site. The exonuclease degrades the nascent RNA until it reaches the stalled Pol II and apparently this facilitates release. This process is called the “torpedo” model of transcription termination. The other commonly accepted model of transcription termination is referred to as the allosteric model

(Logan et al., 1987). In this model, it is not the outside action of an exonuclease that causes the release but the pausing and binding of certain factors that induce an allosteric change in Pol II, facilitating its release from the DNA template on non-poly(A) transcripts. Pcf11, a member of the pA complex, has been shown to dismantle the elongation complex in vitro (Zhang and Gilmour, 2006; Zhang et al., 2007) and Nrd1 may act similarly. The DNA/RNA helicase Sen1 has been proposed to act like the bacterial termination factor rho and pry off the elongating Pol II (Brow, 2011; Kim et al., 1999; Kuehner et al., 2011; Steinmetz and Brow, 1996; Ursic et al., 2004). As there is

evidence for both models of transcription termination, a mixture of both of these models may be correct.

We have previously used a method called Photoactivatable Ribonucleoside-Enhanced Crosslinking and Immunoprecipitation (PAR-CLIP) to map the binding sites of Nrd1, Nab3, Sen1, and Rpb2 throughout the transcriptome (Creamer, 2011; Jamonnak, 2011). PAR-CLIP is a method to crosslink RNA bound to specific proteins following the incorporation of 4-thiouridine (4TU) or 4-thiouracil (4SU) into the transcriptome (Hafner et al., 2010). 4SU is used in yeast because of it can be readily fed into the yeast nucleotide salvage pathway and incorporated into RNA. 4TU is substituted for 4SU in mammalian cells because these cells do not have the correct uracil phosphoribotransferase enzyme for 4SU to be incorporated (Miller et al., 2009).

Nrd1, Nab3 and Sen1 binding sites were mapped genome-wide as the first step to understand more about the NNS pathway (Creamer, 2011). Nrd1 and Nab3 binding sites were found, not only at the 3' end of snoRNA genes, but also at the 5' end of some mRNA genes and antisense to poorly transcribed genes. This allowed us to formulate a model by which the NNS pathway binds early in transcription and monitors the nascent RNA for binding sites. In this way, the NNS complex may act as a checkpoint for proper elongation. In the case of antisense transcripts and some mRNAs, the complex would find it's binding site and terminate the transcript (Creamer, 2011).

In the first part of these studies, we have used PAR-CLIP to map Pol II globally after mutation of both termination pathways in yeast. Although much was learned from the binding sites of Nrd1, Nab3, and Sen1 in vivo from purifying their bound RNAs, their

global effect on transcription remained untested. This was studied by introducing a new system of depleting tagged factors from the nucleus in a time dependent manner termed Anchor Away. The anchor away scheme uses the binding of rapamycin to induce export of a tagged protein out of the nucleus (Haruki et al., 2008). Using anchor away and Pol II PAR-CLIP, we could visualize the affect of termination factor mutation on termination globally. The Cramer lab (Munich) published this idea recently, but they used 4TU-seq to identify the messages affected by Nrd1 depletion (Schulz et al., 2013). Although, both methods use 4TU, we show that they overestimated the effect of Nrd1 mutation because their method was confounded by RNA turnover. We describe a clear definition of termination regions based on the amount of readthrough caused by termination factor depletion (Schaughency, 2014).

Poly(A)-mediated termination is fairly conserved in higher eukaryotes, but it is unclear whether a pathway similar to the NNS modifies ncRNA transcription. snoRNAs are mostly contained within introns of mammalian genes, but the mechanism of snoRNA maturation still requires the nuclear exosome (Berndt et al., 2012; Hirose et al., 2003). Sen1 has a conserved homolog called Senataxin in mammalian cells (Chen et al., 2006). It is unclear whether the putative helicase Senataxin retains a function in processing ncRNAs. Although, mutations in senataxin have been implicated in the cause of certain rare forms of ALS (Anheim et al., 2009; Bassuk et al., 2007; Chen et al., 2006). Nrd1 does have two homologs identified through their similarity in protein domain architecture and conservation of the CTD interacting domain (CID) (Yuryev et al., 1996). These are RBM16 and SFRS15, but little else about their function within the nucleus is known.

In the second part of these studies, we looked at the binding of RBM16 throughout the mammalian transcriptome. Much like the experiments in mapping the yeast binding sites in vivo, this is the first step in formulating a model for the action of these proteins. We find that RBM16 binds to some protein coding genes, ncRNAs, and snoRNAs. These three categories of bound RNAs seem to be conserved from yeast Nrd1. This may suggest a similar mechanism of action. Further mutation studies could illuminate RBM16's function within the nucleus.

For the final part of these studies, we looked at the analyses of PAR-CLIP datasets. PAR-CLIP requires a unique set of programs to accommodate its analysis problems. There is a T -> C transition when the reverse transcriptase makes the cDNA from the crosslinked RNA (Hafner et al., 2010). Although useful in finding exact crosslinking sites, it poses problems for correct alignment of these sequences to the genome. This was solved, by allowing mismatches when mapping these datasets. Another problem was the normalization PAR-CLIP datasets within an experiment. Without normalization of the reads, every dataset would not be comparable to each other. The solution was to multiply every read by the amount of reads mapped per  $10^7$  reads. Unique functions and programs were derived in order to answer basic questions about all these PAR-CLIP datasets. Taken together, these studies have extended the knowledge of termination factors in yeast and mammalian cells.

## **ABSTRACT**

Yeast RNA polymerase II (Pol II) terminates transcription of coding transcripts through the polyadenylation (pA) pathway and non-coding transcripts through the non-polyadenylation (non-pA) pathway. We have used PAR-CLIP to map the position of Pol II genome-wide in living yeast cells after depletion of components of either the pA or non-pA termination complexes. We show here that Ysh1, responsible for cleavage at the pA site, is required for efficient removal of Pol II from the template. Depletion of Ysh1 from the nucleus does not, however, lead to readthrough transcription. In contrast, depletion of the termination factor Nrd1 leads to widespread runaway elongation of non-pA transcripts. Depletion of Sen1 also leads to readthrough at non-pA terminators, but in contrast to Nrd1 this readthrough is less processive or more susceptible to pausing. The data presented here provide delineation of in vivo Pol II termination regions and highlight differences in the sequences that signal termination of different classes of non-pA transcripts.

## **AUTHOR SUMMARY**

Transcription termination is an important regulatory event for both non-coding and coding transcripts. Using high-throughput sequencing, we have mapped RNA Polymerase II's position in the genome after depletion of termination factors from the nucleus. We found that depletion of Ysh1 and Sen1 cause build up of polymerase directly downstream of coding and non-coding genes, respectively. Depletion of Nrd1 causes an increase in polymerase that is distributed up to 1,000 bases downstream of non-coding genes. The depletion of Nrd1 helped us to identify more than 250 unique termination regions for non-coding RNAs. Within this set of newly identified non-coding termination regions, we are further able to classify them based on sequence motif similarities suggesting a functional role for different terminator motifs. The role of these factors in transcriptional termination of coding and/or non-coding transcripts can be inferred from the effect of polymerase's position downstream of given termination sites. This method of depletion and sequencing can be used to further elucidate other factors whose importance to transcription has yet to be determined.

## INTRODUCTION

Termination of RNA Polymerase II (Pol II) transcription plays an essential role in the transcription cycle and has been the subject of several recent reviews (Kuehner et al., 2011; Mischo and Proudfoot, 2013). Disruption of the elongation complex at terminators recycles Pol II maintaining a pool of free enzyme able to compete for unoccupied promoters. Correct termination also prevents Pol II from interfering with expression of downstream genes either by colliding with oncoming Pol II elongation complexes or by dislodging transcription factors from the downstream DNA template (Castelnuovo et al.; Cloutier et al., 2013; Shearwin et al., 2005). Termination can also serve a regulatory purpose. Several yeast genes are regulated by premature termination (Arigo et al., 2006a; Creamer et al., 2011; Kuehner and Brow, 2008) and genes involved in yeast nucleotide metabolism are regulated by the choice of alternative transcription start sites, one of which leads to premature termination (Kuehner and Brow, 2008; Thiebaut et al., 2008). More recent studies have shown that correct termination is also necessary for efficient re-initiation at the same gene through the formation of a loop between the 3' and 5' ends (Grzechnik et al., 2014; Tan-Wong et al., 2012).

In addition to mRNAs, Pol II transcribes a diverse set of non-coding RNAs including snoRNA, some snRNAs and several classes of ncRNA with unknown functions. In yeast, this pervasive transcription (Berretta and Morillon, 2009; Jacquier, 2009; Jensen et al., 2013) falls into several classes. Cryptic unstable transcripts (CUTs) are turned over rapidly by the nuclear exosome (Arigo et al., 2006b; Davis and Ares, 2006; Gudipati et al., 2012; Neil et al., 2009; Thiebaut et al., 2006; Wyers et al., 2005). In contrast, another

class of yeast ncRNA, termed stable uncharacterized transcripts (SUTs) are observed in the presence of an active nuclear exosome (Xu et al., 2009).

Pol II terminates coding and non-coding transcripts by different mechanisms (Buratowski, 2005; Hsin and Manley, 2012; Kim et al., 2006; Kuehner et al., 2011; Mischo and Proudfoot, 2013). Coding transcripts and possibly some SUTs are processed at the 3'-end by the cleavage and polyadenylation (pA) machinery. This reaction is coupled to termination occurring downstream of the processing site (Kuehner et al., 2011; Mischo and Proudfoot, 2013). In contrast, ncRNAs are terminated and processed by an alternative pathway that, in yeast, requires the RNA-binding proteins Nrd1 and Nab3 and the RNA helicase Sen1 (Conrad et al., 2000; Steinmetz and Brow, 1996, 1998; Steinmetz et al., 2001; Ursic et al., 2004).

Yeast Pol II terminators contain short RNA sequences that bind proteins within large complexes associated with the elongating Pol II. Loosely conserved pA signal sequences downstream of protein-coding genes bind to components of the CF1 complex leading to assembly of the cleavage and polyadenylation machinery (Kuehner et al., 2011). Termination is coupled to cleavage in a manner that has not yet been completely resolved. Non-pA termination components Nrd1 and Nab3 recognize RNA sequence elements downstream of snoRNAs and CUTs (Carroll et al., 2007; Carroll et al., 2004; Creamer et al., 2011; Porrua et al., 2012; Steinmetz et al., 2001; Steinmetz et al., 2006a; Wlotzka et al., 2011) and this leads to the association of a complex that contains the DNA/RNA helicase Sen1 and the nuclear exosome (Vasiljeva and Buratowski, 2006). The mechanism of termination of these ncRNA transcripts has also not yet been determined.

Several possible mechanisms for Pol II termination have been proposed. The “torpedo” model postulates that cleavage at the pA site exposes an uncapped 5’ end on the nascent transcript that acts as a substrate for the 5’  $\rightarrow$  3’ RNA exonuclease Rat1 in yeast or Xrn2 in metazoans (Brannan and Bentley, 2012; Kim et al., 2004b; West et al., 2004). The exonuclease degrades the nascent transcript and upon reaching the Pol II elongation complex facilitates termination by an unknown mechanism. Another model postulates that an allosteric change in Pol II occurs upon assembly of the pA complex (Logan et al., 1987). A member of this complex, Pcf11 has been shown to dismantle an elongation complex in vitro (Zhang and Gilmour, 2006; Zhang et al., 2007) and it is possible that Nrd1 plays a similar role. The DNA/RNA helicase Sen1 interacts with the Pol II CTD (Chinchilla et al., 2012) and has been proposed to act like the bacterial termination factor rho and track along the nascent transcript and pry off the elongating Pol II (Brow, 2011; Kim et al., 1999; Kuehner et al., 2011; Steinmetz and Brow, 1996; Ursic et al., 2004). Mutation of Sen1 has been shown to lead to readthrough of both coding and non-coding transcripts in vivo (Steinmetz et al., 2006b) and in vitro can arrest transcription (Porrua and Libri, 2013).

Part of the uncertainty in delineating termination mechanisms is identifying which factors operate at which terminators in vivo. In this study we have used PAR-CLIP to map Pol II on the yeast genome in living cells (Creamer et al., 2011; Hafner et al., 2010a, b; Jamonnak et al., 2011) after depletion from the nucleus of components of the different termination pathways (Haruki et al., 2008). By comparing the Pol II maps with and without nuclear depletion we are able to map the location of termination to narrow regions of the genome downstream of coding and non-coding genes. This approach

avoids the complexity of using transcripts to map terminators as the effect of RNA turnover is eliminated. We show here that depletion of Ysh1, the protein that cleaves nascent pre-mRNA transcripts at the pA site, enhances accumulation of Pol II at the 3'-ends of protein-coding genes. In contrast, both Nrd1 and Sen1 depletion lead to readthrough transcription of ncRNAs and our data has allowed us to map the position of non-pA termination facilitated by these factors.

## RESULTS

### Mapping in vivo Pol II termination

To map in vivo termination we have used the anchor-away (AA) system (Haruki et al., 2008) to deplete termination factors from the nucleus. In this approach rapamycin (rap) induces a complex between a protein tagged with a FKBP12-rapamycin binding (FRB) domain and an anchor protein tagged with an FKBP12 domain. In our case the FKBP12 domain is on the ribosomal protein *RPL13A* leading to rap-dependent depletion of FRB-tagged protein from the nucleus. Previous work has shown that a Pol II subunit *RPB1-FRB* strain shows greater than 90% depletion of Pol II at the *PMA1* gene within 40 min (Fan et al., 2010). We show here that in *NRD1-FRBGFP* or *YSH1-FRBGFP* strains that also contain, *RPB3-TAGRFP*, Nrd1 and Ysh1 are depleted from the nucleus with similar kinetics (Figure 1A-B). We were unable to observe Sen1-FRBGFP because it is present only in ~100-2,000 copies per cell. When over-expressed 10-100-fold from a Gal promoter Sen1-FRBGFP is visible and is depleted from the nucleus with similar kinetics (Figure 1C). Given the limitations of background signals in live-cell imaging we cannot rule out the possibility that some small amount of Nrd1, Ysh1 or Sen1 remain in the nucleus. Growth curves show that all three strains grow normally for several divisions after administration of rap and we carried out PAR-CLIP analysis well before any changes in growth were observed (Figure 2A, shaded box). When cells are plated on media containing rap we observe no growth for *YSH1-FRB* and *NRD1-FRB*, while *SEN1-FRB* grows very slowly (Figure 1D).

Growing yeast cultures were cross-linked as previously described (Creamer et al., 2011; Jamonnak et al., 2011) with modifications described in Methods. Briefly, 4-

thiouracil (4tU) was added to a growing culture for 15 minutes to allow equilibration of uracil pools before the addition of rap. After thirty minutes of rap treatment cultures were irradiated with 365 nm UV for 15 min (Figure 2B). Incubation of yeast cells in 4tU does not significantly affect growth during the course of the experiment as cells continue to grow beyond the time frame of the cross-linking for at least one more doubling (0.2 OD<sub>600</sub> to 0.7 OD<sub>600</sub> as measured by BioTek scanner) indicating that 4tU has a less drastic effect on yeast growth than it does in mammalian cells treated for a longer time (Burger et al., 2013).

To map the position of elongating Pol II we isolated Pol II-bound RNA using a dual 6xHis-biotin tagged Pol II Rpb2 subunit (Rpb2-HTB) as previously described (Creamer et al., 2011). Duplicate libraries were derived from the *RPB2-HTB NRD1-FRB* strain grown in the presence or absence of rap. We also created libraries of Rpb2-bound RNA from *SEN1-FRB* and the parental *RPB2-HTB* strains grown in the presence of rap and a single library from *YSH1-FRB*. Replicate libraries were multiplexed and sequenced by Illumina Hi-seq. Each library yielded between 15-39 million unique reads (Table 1). Biological replicates were strongly correlated ( $r > .99$ ) and thus were added together for analysis (Figure 3). The WT dataset correlates very well to NET-seq (Churchman and Weissman, 2011) and GRO-seq (Pelechano et al., 2010) datasets (Figure 4). Thus, PAR-CLIP data accurately represents the position of Pol II elongation complexes on the yeast genome.

### **Ysh1-dependent termination**

To map pA-dependent termination we carried out PAR-CLIP on Rpb2 after depletion of Ysh1, the factor that has been shown to be required for cleavage of the nascent mRNA at the *GAL7* and *CYC1* pA sites (Zhelkovsky et al., 2006). We reasoned that failure to cleave the nascent transcript would prevent Rat1 degradation thus disabling the “torpedo” mechanism. While we cannot rule out the possibility that other factors are depleted along with Ysh1 we do observe a failure to cleave at the pA site for several genes (Figure 5). The most dramatic effect of Ysh1 depletion is seen in a buildup of reads just downstream of the major pA site of highly expressed protein-coding genes (Figure 6A and 2C). The peak of reads is present in most of the highly expressed protein-coding genes as seen in figure 6B. No similar effect is seen downstream of snoRNAs or CUTS. One surprising aspect of Ysh1 depletion is that readthrough Pol II does not extend further downstream but seems to pause or terminate within 200 bp of the pA site (Figure 6A). This result indicates that Pol II that reads through termination signals fails to elongate but is unable to efficiently terminate.

We do, however, observe several instances of Pol II extending 1 kb or more downstream of apparent terminators in response to Ysh1 depletion. The *RNAI4* and *DBP2* genes show an increase of Pol II toward the 3' end of the coding region indicating the presence of a Ysh1-dependent terminator upstream of the main pA site (Figure 6D). Rna14p is part of the CF1 complex required for recognition of pA sites (Kuehner et al., 2011) and previous studies have shown that in addition to the mature 2.2 kb mRNA several smaller mRNAs are present under normal conditions (Brendolise et al., 2002; Mandart, 1998). The terminator we map in *RNAI4* is located in the same region as the 3' end of the shorter (1 kb) mRNA (Figure 6D).

Dbp2p is a DEAD-box RNA helicase that plays a role in assembly of mRNP complexes and in RNA quality control (Cloutier et al., 2012; Ma et al., 2013). The *DBP2* gene is unique in yeast in having a long (1kb) intron localized toward the 3' end of the coding region and previous work has shown that the gene is autoregulated through sequences in the intron (Barta and Iggo, 1995). In Figure 6D we show that depletion of Ysh1 leads to an increase in Pol II cross-linking downstream of the intron suggesting the presence of an upstream terminator. Consistent with this view polyadenylation sites have been mapped to this location in the Dbp2 intron (Moqtaderi et al., 2013; Ozsolak et al., 2010; Wilkening et al., 2013).

### **Nrd1-dependent termination**

Previous work has shown that Nrd1p is required for proper termination of ncRNAs like snoRNAs and CUTs as well as premature termination of coding transcripts of genes regulated by attenuation (Arigo et al., 2006a; Kuehner and Brow, 2008; Steinmetz et al., 2001; Thiebaut et al., 2008; Thiebaut et al., 2006; Vasiljeva and Buratowski, 2006; Vasiljeva et al., 2008). Here we show that depletion of Nrd1 in the presence of rap leads to readthrough transcription of a large number of these ncRNAs. Similar results have recently been obtained by a different protocol (Schulz et al., 2013).

To map the position of termination we used an approach similar to that used to calculate a travelling ratio (Rahl et al., 2010) or Escape Index (Brannan and Bentley, 2012; Schulz et al., 2013). Reads in 500 bp windows upstream and downstream of a fixed point were tallied and a ratio of reads in the downstream window to total reads in both windows were calculated for that point. This ratio was determined for each point in

the genome on both strands for both control and rap treated cells. Subtracting the fraction of readthrough of the control data from the rap-treated data resulted in a Readthrough Index that allowed us to rank order the regions of the genome showing the highest level of Nrd1-dependent readthrough (Table 2).

Once these regions were identified, we created plots of the difference between the reads in the control and reads with rap (Figure 7A). Nrd1 depletion leads to both a reduction of Pol II upstream and an increase of Pol II downstream of apparent termination sites. This is consistent with previous reports that Pol II pauses prior to termination (Gromak et al., 2006; Hyman and Moore, 1993; Kazerouninia et al., 2010; Larson et al., 2011). In the absence of Nrd1, this apparent pause is eliminated and Pol II is able to transcribe through the termination site. Fitting this difference plot with a spline function allowed us to determine the point at which the difference plot crosses the X-axis. We have called this the termination site but this represents the center point of a narrow (about 50 nt) region over which Pol II is released from the template.

In Figure 7A we show the difference plots for snoRNA *snR34* and the antisense CUT to the *LEO1* gene demonstrating how the termination sites were identified. We have carried out this analysis for 49 snoRNAs and for 144 CUTs showing the highest level of readthrough transcription (Tables S2 and S3). Comparing these termination sites to the sites determined by Pol II ChIP (Schulz et al., 2013) reveals that 70% of the Schulz et al. sites are more than 100 nt downstream of our termination sites and 25% are more than 200 nt downstream (Figure 8). We do not know the reason for this systematic discrepancy but the PAR-CLIP analysis has greater resolution than Pol II ChIP and unlike ChIP gives strand-specificity. The metagene analysis of the ncRNAs for which we

have mapped termination sites is shown in Figure 7B demonstrating a more significant increase in readthrough transcription for Nrd1-depletion when compared to the increase in readthrough transcription due to Ysh1 depletion (Figure 6A). SnoRNA and CUT Nrd1-dependent readthrough extends over 500bp and 1 kb, respectively.

Examining DNA sequences upstream of the termination site for these sets of snoRNAs and CUTs revealed an interesting difference in the occurrence of Nrd1 and Nab3 binding motifs. The top hit in the MEME analysis (Bailey et al., 2009) of the top 27 snoRNA upstream regions (Figure 7C) include the GUA[A/G] sequence previously identified as a Nrd1 binding site (Bacikova et al., 2014; Carroll et al., 2007; Carroll et al., 2004; Creamer et al., 2011; Porrua et al., 2012; Wlotzka et al., 2011). This analysis also identifies a loosely conserved sequence AACUA centered about seven nucleotides upstream of the GUA[A/G] sequence that has not previously been reported. The second most significant motif upstream of the snoRNA termination site was the UCUU sequence that binds Nab3, consistent with the presence of a Nrd1-Nab3 heterodimer (Carroll et al., 2007; Conrad et al., 2000). In sequences upstream of CUT terminators the most significant hit was UCUUG which contains the previously identified Nab3-binding sequence but with a downstream G as has been observed previously (Creamer et al., 2011; Porrua et al., 2012; Wlotzka et al., 2011). Among the 144 CUT terminators the Nrd1 binding motif was not present above background. Together, these observations suggest a significant difference in the manner of recognition of snoRNA and CUT terminators.

### **U-rich sequences in the Nrd1-dependent termination region**

In Figure 9 we show NET-seq (Churchman and Weissman, 2011) and PAR-CLIP data demonstrating that Pol II levels decline in the *SNR13-TRS31* intergenic region. NET-seq reads for several peaks, indicated by bars, are reduced several-fold immediately downstream from the 3'-end of the *SNR13* gene and more than 6-fold further than 100 nt downstream. PAR-CLIP reads from cells grown in the absence of rap decline at the same region reaching a minimum at about 150 nt downstream of the *SNR13* 3'-end. A similar correspondence between NET-seq and PAR-CLIP data is seen for other snoRNA genes (Figure 10). Taken together, these observations indicate that Pol II normally terminates in a Nrd1-dependent fashion in a narrow region located downstream of the snoRNA gene. The sequence from this region for *SNR13*, located from 50 – 150 nt downstream, is shown below the figure and a series of runs of U residues is indicated in red. This is not unexpected as intergenic regions in *S. cerevisiae* are AT-rich. Sequences of termination regions of several antisense CUTs are shown below the *SNR13* sequence. In these cases we also observe runs of U residues. This is unexpected as these termination regions fall within coding regions (on the opposite strand) which in general are not AT-rich. We propose that these U-rich regions constitute part of the non-poly(A) terminator.

### **Nrd1 and RNA turnover**

We estimate that *SNR13* readthrough transcripts are present at less than one copy per cell in wild-type cells and this is consistent with the low level of readthrough transcripts seen in the absence of rap in the Northern blot shown in Figure 11A. Despite this low level of steady-state readthrough transcripts we observe significant cross-linking to Rpb2 in the region downstream of *SNR13* (Figure 11B) even in the presence of Nrd1. Presumably the RNA synthesized by these polymerases is rapidly degraded by the

nuclear exosome. Figure 11A shows that snR13 readthrough transcripts detected by Northern blot or RT-PCR are increased more than 10-fold by 15 min and more than 100-fold by 30 min of Nrd1 depletion. However, depletion of Nrd1 results in only a 2-3-fold increase in PAR-CLIP signal for Rpb2 (Figure 11B) indicating that depletion of Nrd1 not only allows readthrough of ncRNA transcripts but also results in their stabilization by uncoupling degradation by the nuclear exosome.

Our analysis of steady-state RNA levels is consistent with recently published 4tU-seq data (Schulz et al., 2013). Figure 11C shows the comparison of our data and that of Schulz et al for *SNR13* and the upstream *RPL27B* gene and for the *SNR62* and *SNR9* genes. 4tU-seq data show a dramatic increase in *SNR13* and *SNR62* readthrough transcription compared to PAR-CLIP data. The most likely explanation for this difference is that 4tU labeling is not completely restricted to nascent transcripts. Labeling cells for six minutes with 4tU allows for multiple rounds of transcription especially for heavily transcribed genes like snoRNAs and ribosomal protein genes. The earliest synthesized transcripts are subject to processing as is clearly evident in the paucity of reads derived from the intron of *RPL27B* in the 4tU-seq compared to the PAR-CLIP (Figure 11C) and a number of other intron-containing genes (Figure 12). Depletion of Nrd1 does not effect all snoRNAs as is seen in Figure 11C where neither PAR-CLIP nor 4tU-seq detect appreciable readthrough transcription at *SNR9*.

### **Sen1-dependent termination**

A role for Sen1p in termination of both coding and ncRNA transcripts has been proposed (Steinmetz and Brow, 1996; Steinmetz et al., 2001; Steinmetz et al., 2006b). Our current

data show that depletion of Sen1 results in no change in the localization of Pol II at the 3'-ends of most protein-coding genes (Figure 13A) including those previously shown (Steinmetz et al., 2006b) to be dependent on Sen1 (Figure 14). Thus, despite our previous observation that Sen1 cross-links to these transcripts (Creamer et al., 2011), there is little evidence for a role for Sen1 in pA termination. Sen1 depletion does result in readthrough transcription at both snoRNAs and CUTS (Figure 13B-C) which is consistent with previous observations (Arigo et al., 2006b; Steinmetz et al., 2001; Thiebaut et al., 2006). The pattern of Pol II readthrough in response to Sen1 depletion differs, however, from that of Nrd1. Rather than an extended region of readthrough downstream of the terminator, Sen1 depletion often results in an increase just downstream by a few hundred nucleotides. This type of pattern is seen in Figure 13D for *SNR47* and the CUT antisense to the *COG8* gene and in Figure 15 for several protein-coding genes regulated by Nrd1-dependent attenuation. Figure 13E compares the percent readthrough downstream of all 266 non-pA terminators in Sen1 depleted and Nrd1 depleted cells. The percent readthrough after Nrd1 depletion is twice that for Sen1 depletion and these values are not dominated by a subset of terminators. This observation suggests that Sen1 may play a different function than Nrd1 at these genes and that loss of Sen1 results in less processive or more pause prone readthrough transcription.

## **DISCUSSION**

In this paper we describe the development and implementation of a technique for mapping the position of in vivo Pol II termination. Depletion of components of the yeast Pol II termination machinery followed by Pol II cross-linking to nascent RNA has allowed the identification of both pA and non-pA termination regions. The site of pA termination has been mapped to within a few hundred bases of the pA site as has previously been observed for the Cyc1 terminator (Birse et al., 1998). We have identified non-pA terminators using an algorithm that identifies points in the genome where Pol II readthrough increases in response to Nrd1 depletion.

While many of the components of both the pA and non-pA termination complexes have been identified, the mechanism of termination is still unclear. Two general models have been proposed (Buratowski, 2005; Kuehner et al., 2011; Luo and Bentley, 2004; Mischo and Proudfoot, 2013). The allosteric model proposes a conformational change in Pol II that slows elongation (Calvo and Manley, 2001; Logan et al., 1987; Nag et al., 2006) while the torpedo model proposes that cleavage at the pA site creates a substrate for a 5' → 3' exonuclease (Rat1 in yeast and Xrn2 in metazoa) that degrades the nascent transcript like a “fuse” and upon reaching elongating Pol II somehow facilitate termination (Connelly and Manley, 1988; Kim et al., 2004b; West et al., 2004). Neither model adequately explains all experimental observations leading to a hybrid model that includes both allosteric and torpedo mechanisms (Luo et al., 2006).

### **pA Termination**

Our data on Ysh1 depletion supports a two-step pause and release model for termination that invokes both allosteric and torpedo mechanisms (Nag et al., 2007). The buildup of

Pol II just downstream of the uncleaved pA site suggests that Pol II has paused but is deficient in the subsequent release step. This is consistent with a role for Ysh1 in providing the substrate for the Rat1 exonuclease that facilitates removal of Pol II from the template (Pearson and Moore, 2013). Ysh1 apparently is not required for the allosteric change that results in pausing downstream of the pA site as seen in the lack of readthrough at most pA sites. In contrast, mutation of the pA site (Kim et al., 2004a) or mutations in *RNAI4*, *RNAI5*, *PCF11*, *CLP1* and *GLC7* result in readthrough transcription more than 500 nt downstream (Al Husini et al., 2013; Birse et al., 1998; Schreieck et al., 2014) arguing for a role for these factors in the allosteric change that renders Pol II immobilized.

Depletion of Ysh1 has also revealed several genes that are apparently regulated by premature termination through the pA pathway. *RNAI4* and *DBP2* contain pA sites upstream from the 3' pA site. Loss of Ysh1 leads to processive elongation ending at the downstream pA site indicating that Ysh1 is required for termination at these upstream sites. Why the putative allosteric step does not function efficiently at these upstream sites is not clear. Perhaps the phosphorylation pattern of the CTD at these sites precludes the assembly of factors like Pcf11. Alternatively, chromatin structure modification induced by the Pol II that elongates through these terminators may suppress normal termination. Finally, it is possible that use of the downstream terminator by Pol II that ignores the upstream pA site creates a gene loop that favors termination at the downstream site.

### **Non-pA Termination**

Nrd1 and Nab3 bind specific RNA sequences and act as sensors to detect non-pA terminator sequences in the nascent transcript. While a number of studies have characterized the short motifs recognized by Nrd1 and Nab3 the relative orientation and abundance of these sequences varies widely among non-pA terminators (Carroll et al., 2007; Carroll et al., 2004; Creamer et al., 2011; Jamonnak et al., 2011; Porrua et al., 2012; Schulz et al., 2013; Wlotzka et al., 2011). In this study we have localized termination downstream of 49 snoRNAs and 144 CUT transcripts. This has allowed a search for sequences that may define these two sets of terminators. We find that the most significant motif in this set of snoRNA terminators contains the GUA[A/G] motif previously identified for Nrd1 in the context of a longer sequence that indicates the possible involvement of another, unidentified RNA-binding protein. The second most significant motif is the Nab3 binding sequence UCUUG. In the case of the CUT terminators the only significant motif is the Nab3 binding sequence. Thus, it appears that while both Nrd1 and Nab3 binding contribute to recognition of snoRNA terminators Nab3 predominates for CUTs. This does not preclude Nrd1 from playing a critical role in termination at these CUTs. We have previously shown that Nrd1 is necessary for termination of the CUT antisense to *FMP40* presumably by acting as an adaptor to couple the Nrd1-Nab3-Sen1 complex to the elongating Pol II through interaction between the Nrd1 CID and the CTD (Arigo et al., 2006b).

No other significant motifs were observed upstream of these terminators but we did observe that the sequences surrounding the termination site are U-rich and contain multiple runs of U residues. This is not unexpected for snoRNA downstream sequences as intergenic regions are AT-rich in *S. cerevisiae*. The U-rich sequences surrounding the

termination sites (Figure 9) of antisense CUTs are more significant as these sequences occur in the context of a coding region on the opposite strand. U-rich sequences have been shown to form unstable rU:dA base pairs (Huang et al., 2010) and in the hybrid binding site of Pol II transcribing the antisense CUT such an unstable hybrid sequence may increase the probability of termination (Kireeva et al., 2000; Martin and Tinoco, 1980).

In addition to its role in Pol II termination, our data highlight the role Nrd1 plays in the turnover of ncRNAs. Nrd1 depletion by anchor away leads to accumulation of readthrough transcripts in 4tU-seq to a much higher degree than observed by our Rpb2-HTB PAR-CLIP. We show here by Northern and RT-PCR that after 40 min of Nrd1 depletion the level of snR13 readthrough transcripts increases over 100-fold. However, after 40 minutes of depletion the amount of readthrough as observed by PAR-CLIP is less than 10-fold. This difference is likely due to an important role for Nrd1 in coupling termination to turnover of the completed transcript. Nrd1 is found in a complex with components of the TRAMP and exosome complexes (Vasiljeva and Buratowski, 2006) and previous studies have indicated that *nrd1* mutants are deficient in RNA turnover (Arigo et al., 2006b; Thiebaut et al., 2006; Vasiljeva and Buratowski, 2006).

Pulse labeling RNA with 4tU was recently used to analyze newly synthesized transcripts in a Nrd1 anchor away mutant and this data identified over 1500 Nrd1-dependent transcripts (Schulz et al., 2013), far more than the number of terminators we describe here. Part of the reason for this discrepancy is that the six-minute pulse used in the 4tU-seq protocol is substantially longer than the time needed to synthesize short

RNAs. Thus, 4tU-seq over-estimates the effect on termination and may ascribe termination functions to cases where the role in turnover is independent of termination.

Depletion of the DNA/RNA helicase Sen1 has allowed us to place this factor squarely in the Nrd1-Nab3 non-pA termination pathway. We observe readthrough transcription downstream of both snoRNAs and CUTs but not downstream of pA sites. Pol II does not progress far downstream after Sen1 depletion indicating that this factor may act after the allosteric change has occurred. This is consistent with Sen1 acting in place of Rat1 to provide the activity that dislodges the paused Pol II (Porrua and Libri, 2013) and supports previous work showing the difference in the requirement for these factors in pA and non-pA termination (Kim et al., 2006).

The results presented here are summarized in a model shown in Figure 16. We have been able to demonstrate a difference in the global effect of depleting different components of the yeast termination machinery. These results have been interpreted in the context of a two state model for termination in which terminator sequences in the nascent RNA trigger assembly of protein complexes that signal to the elongating Pol II to decrease its elongation rate and processivity. These anti-processivity factors include Pcf11 for pA terminators and Nrd1 for non-pA terminators. Loss of either of these factors leads to runaway processive elongation. In contrast, depletion of Ysh1 or Sen1 does not block the transition to non-processive elongation but does result in a defect in removal of Pol II from the template. For Sen1 this likely occurs through loss of a rho-like function (Brow, 2011; Porrua and Libri, 2013) while Ysh1 depletion leads to a lack of cleavage at the pA site thereby limiting access of Rat1 and preventing the torpedo mechanism of Pol II release (Pearson and Moore, 2013).

The data presented here demonstrate that PAR-CLIP analysis of Pol II in living yeast cells can define the site of Pol II termination regions and when coupled with depletion of termination factors offers an avenue for examining the roles of different factors in termination genome-wide. Such experiments will illuminate the variety of mechanisms the cell uses to prevent Pol II from transcribing beyond genetically determined 3' boundaries.

## **MATERIALS and METHODS**

### **Strain Construction**

Yeast strains for anchor away were constructed using the parental strain HHY168 (Haruki et al., 2008) (Euroscarf #Y40343). *RPB2* was C-terminally tagged with an HTB (6xHIS, TEV, and Biotin) tag as described previously (Creamer et al., 2011; Tagwerker et al., 2006). *NRD1*, *YSH1*, and *SEN1* were C-terminally tagged with FRB and FRBGFP as described in Haruki et al. (Haruki et al., 2008). The *SEN1* promotor was replaced with the *GAL1* promotor using a cassette from pFA6a-kanMX6-PGAL1-HBH (Tagwerker et al., 2006). All strains used in these experiments are listed in Table 4.

### **Cell Growth**

Cells were grown in Complete Synthetic Media (CSM) supplemented with 2% glucose or galactose and 40 mg/l adenine. For RNA analysis, cells were seeded to an OD<sub>600</sub> of 0.1 from a 5 ml or 50 ml overnight culture. The cells were then incubated at 30°C to an OD<sub>600</sub> of 1. 1 µg/ml of rap (LC laboratories) was then added to the cultures and the cells were allowed to grow for the indicated times in the experiment. For growth curves, a BioTek Infinity 2 (BioTek) was used to incubate a 24 well plate containing CSM media with and without 1 µg/ml rap (added after 6 hrs of growth) with orbital shaking (Slow, 1 mm amplitude). Cells were diluted to an OD<sub>600</sub> of 0.1 per well and an OD<sub>600</sub> was measured every 10 min for 24 hours.

### **RNA Purification and cDNA synthesis**

Total RNA was extracted from yeast with hot acid phenol as previously described (Creamer et al., 2011). Strand specific northern blots were done as described previously

(Marquardt et al., 2011) with the following modifications. Ultrahyb (Invitrogen) was used instead of the described hybridization buffer. Real-time PCR analysis was done on a CFX96 instrument (Biorad) in triplicate as described previously (Jamonnak et al., 2011). Primers used can be found in Table 5.

### **Live Cell Imaging of FRBGFP Strains.**

The strains containing *NRD1-FRBGFP*, *YSH1-FRBGFP*, or *GALpSEN1-FRBGFP*, *RPB3-TAGRFP* were grown to an OD<sub>600</sub> of 1 at 30°C. Live cell imaging was done on a Deltavision microscope (Applied Precision) as described previously (Rines et al., 2011) with the following modification: 1 µg/ml rapamycin was added to the agarose/media pad. Galactose was substituted for glucose with the GALpSEN1-FRBGFP strain. Pictures were taken of GFP at 0 mins and 45 mins post rap exposure and 45 mins for RFP.

### **Anchor Away and PAR-CLIP**

Cells were grown overnight 30°C in 50 ml of YPD (Yeast Extract Peptone with 2% glucose) media. Four 500 ml flasks of sterile cross-linking media (CSM-Ura supplemented with 2% glucose, 40 mg/l adenine, 60 µM uracil, and 1 µM biotin) were seeded to an OD<sub>600</sub> of 0.1 and incubated at 30°C until an OD<sub>600</sub> of 1. Crosslinking was carried out by the protocol described in Figure 2B. 4-thiouracil (4tU) was added to a final concentration of 4 mM and incubated at 30°C for 15 min. 1 µg/ml of rapamycin was then added to the cells and incubated at 30°C for 30 min. All four 500 ml cultures were then pooled into one 2 l beaker and irradiated from a distance of two cm with 365 nm UV (~ 1 W/cm<sup>2</sup>) from an LC-L5 LED UV Lamp (Hamamatsu) for 15 min with gentle stirring. The top ~2 mm of the culture appears luminescent indicating that the UV light does not

penetrate further into the culture. Assuming an even mixture of the culture we calculate that the average cell is cross-linked for only ~ 10 seconds within the 15 min crosslinking period. The cultures were then filtered through 0.45 micron nitrocellulose filters (Millipore) and cells were scraped into 5 ml Buffer 1 (300 mM NaCl, 0.5% NP-40, 50 mM NaPO<sub>4</sub> pH 7.2, 10 mM imidazole, 6 M Guanidine HCl, Protease inhibitor Cocktail VII [RPI]) and frozen in liquid nitrogen.

HTB tagged Rpb2 purification was adapted from our previously published protocol (Jamonnak et al., 2011). Cells were lysed in liquid nitrogen using a SamplePrep 6870 freezer mill (Spex) with 15 cycles per second of cracking for 15 cycles of 1 min with 2 min of cooling between each cycle. Lysates were then incubated with 1 ml of Ni-NTA agarose (Qiagen), which was equilibrated in buffer 1 for 2 hours at room temperature. The Ni-NTA agarose was then added to an empty 10 mL plastic column (Biorad) and washed with 20 ml of Buffer 1 followed by 10 ml of Buffer 2 (20 mM NaPO<sub>4</sub> pH 7.2, 300 mM NaCl, 0.5% NP40, 10 mM imidazole, 4 M Urea). The protein was eluted off of the Ni-NTA agarose with 5 ml Buffer 2 + 250 mM imidazole and into 5 ml Buffer 2 + 120 µl Protease inhibitor Cocktail VII + 100 µl of hydrophilic streptavidin magnetic beads (NEB). The slurry was allowed to incubate for 4 hours at room temperature. The strepavadin magnetic beads were then resuspended in 500 ul of Buffer 3 (50 mM Tris pH 7.4, 200 mM NaCl, 4 M Urea), transferred to a 1.5 ml siliconized tube and washed with 3 x 1 ml of Buffer 3 followed by 3 x 1 ml of T1 Buffer (50 mM Tris pH 7.4, 150 mM NaCl, 2 mM EDTA). Beads were resuspended in 200 µl of T1 buffer. 0.15 U/µl of Rnase T1 (Fermentas) was added to the bead slurry and allowed to incubate at 25°C for 15 min. The beads were then washed 3 x 1 ml T1 wash buffer (50

mM Tris pH 7.4, 500 mM NaCl, 1% NP-40, 0.5% Na deoxycholate) followed by 3 x 1 ml washes in PNK Buffer (50 mM Tris pH 7.2, 50 mM NaCl, 10 mM MgCl<sub>2</sub>). The beads were resuspended in 200 µl of TSAP reaction solution (0.15 U/µl Thermosensitive Alkaline Phosphatase [TSAP, Promega], 1 U/µl Suprase Inhibitor [Invitrogen], 1 mM DTT in PNK Buffer) and incubated at 37°C for 30 min. The beads were washed 1 x 1 ml Buffer 3, 2 x 1 ml T1 Wash Buffer, and 3 x 1 ml PNK Buffer.

### **cDNA Library Preparation**

Streptavidin beads were resuspended in 200 µl of PNK reaction solution (1 U/µl T4 PNK [NEB], <sup>32</sup>P g-ATP, 5 mM DTT in PNK Buffer) and incubated at 37°C for 30 min. 1 mM of cold ATP was added to the reaction and incubated at 37°C for 10 min. The beads were washed 1 x 1 ml Buffer 3, 1 x 1 ml T1 wash, 3 x 1 ml T4 RNA Ligase Buffer (50 mM Tris pH 7.4, 10 mM MgCl<sub>2</sub>). The beads were resuspended in 44 µl of T4 RNA Ligase 2 reaction solution (25% PEG 8000, 5 µM 3' adaptor [AppAGATCGGAAGAGCACACGTCTddC, IDT], 10 U/µl T4 RNA Ligase 2, truncated K227Q [NEB], 2 U/µl RNase Inhibitor [Invitrogen], 1 mM DTT in RNA Ligase Buffer) and incubated at 25°C for 4 hours. The beads were then washed with 1 x 1 ml Buffer 3 and 5 x 1 ml T4 RNA Ligase Buffer. The beads were resuspended in 50 µl of T4 RNA Ligase reaction solution (5 µM 5' Adaptor [GUUCAGAGUUCUACAGUCCGACGAUC, IDT], 1.2 U/µl RNase Inhibitor, 1mM ATP, 0.5 U/µl T4 RNA Ligase [NEB], 1 mM DTT in RNA Ligase Buffer) and incubated at 16°C overnight. The beads were then washed 5 x 1 ml Proteinase K Buffer (100 mM Tris pH 7.4, 150 mM NaCl, 12.5 mM EDTA). The beads were resuspended in 200 µl of Proteinase K Buffer + 2% SDS and 12 µl of Proteinase K (NEB). The suspension was incubated for 30 min at 37°C at which point the

supernatant was removed and saved and the beads were resuspended in 200  $\mu$ l of Proteinase K Buffer + 2% SDS and 12  $\mu$ l of Proteinase K. The beads were then incubated 30 min at 37°C and the supernatants were pooled. The RNA was recovered by acid phenol/chloroform extraction followed by two serial ethanol precipitations. The resulting pellet was allowed to dry and resuspended in 15  $\mu$ l of Nuclease-Free Water [Invitrogen]. The RNA was split into 5  $\mu$ L aliquots and frozen at -80°C for storage.

The Reverse Transcription, PCR, and gel extraction of the cDNA Library were carried out as described previously (Jamonnak et al., 2011) with the following modifications. For reverse transcription, the primer used was AGACGTGTGCTCTTCCGATCT (IDT). For PCR analysis, biological repeats were multiplexed with the following primers. The forward primer was

AATGATACGGCGACCACCGAGATCTACACGTTGAGAGTTCTACAGTCCG\*A

(where a \* denotes a phosphorothioate bond). The first reverse primer was

CAAGCAGAAGACGGCATACGAGATATTGGCGTGACTGGAGTTCAGACGTGTG

CTCTTCGGATC\*T for the first biological repeat and the second reverse primer was

CAAGCAGAAGACGGCATACGAGATTACAAGGTGACTGGAGTTCAGACGTGT

GCTCTTCCGATC\*T for the second biological repeat (IDT).

### **Sequencing and Bioinformatics**

Sequencing and demultiplexing was done at UC Riverside on an Illumina HiSeq.

Trimming of the resulting sequences as described previously (Jamonnak et al., 2011).

Briefly, raw reads were trimmed of the 3' adaptor using a wrapper for R-bioconductor (Gentleman et al., 2004) developed by Sarah Wheelan. Raw trimmed reads were

condensed (defined as no more than one of the same exact sequence) to eliminate any PCR artifacts within the data. Bowtie 1.0.0 (Langmead, 2010) was run with the following arguments (-y --best -v 2) and aligned to the SacCer3 (R64) genome. Reads mapping to tRNA genes were removed as these likely represent artifactual binding during the affinity purification steps. Reads were then converted to a wig format where each read was multiplied by a factor that was defined as the total number of reads aligned per  $10^7$  reads. PAR-CLIP datasets have been submitted to GEO with the accession number GSE56435.

### **Calculation of the Top 500 PolyA Sites.**

To calculate the best polyA sites per gene we used the sites provided by Moqtaderi et al. (Moqtaderi et al., 2013). We set a hard cutoff of at least 200 raw reads. If, however, there were multiple very strong polyA sites within 200 base pairs of each other, we calculated the read ratio between the two most significant polyA sites. If the read ratio was less than 0.4, we ignored them.

### **Global Readthrough Percentage**

Global readthrough percentage was calculated for each point in the genome as the percentage readthrough (reads downstream 500 bp / reads downstream 500 bp + reads upstream 500 bp) in the treated sample minus control sample. All points with a percentage readthrough of greater than 10%, at least a total of 1000 reads in either sample, and greater reads in the treatment vs the control were extracted. The list was further refined by taking the difference of every point 2 kb around non-overlapping termination sites (approx 500 total), graphing the region, and then fitting a spline function over a 25

bp window to find the best point of inflection. These points of inflection were then used as a focal point for the meta gene analysis.

## **Acknowledgements**

We thank Dr. Sarah Wheelan (Johns Hopkins) for the 3' trimming program and Dr. Andrew Holland (Johns Hopkins) for use of the microscope. Professor Patrick Cramer (Gottingen) provided access to 4tU-seq data and helpful comments on the manuscript. Jennifer Fairman (Johns Hopkins) provided illustrations. Dr. Nicholas Guydosh (Johns Hopkins) provided helpful comments on the manuscript.

**Figure 16. Schematic representation of Pol II termination after removal of non-pA and pA termination factors.**

Elongating Pol II (green) terminates pA transcripts (A) after an allosteric change (red) that reduces processivity. (B) Depletion of Ysh1 leads to minimally extended readthrough transcripts but does not block the allosteric change in Pol II. (C) Nrd1 and Nab3 binding recruit Sen1 for termination of non-pA transcripts. (D) Pol II elongation complex lacking Nrd1 does not recognize termination sequences in the nascent transcript and thus does not facilitate the allosteric transition in Pol II. This leads to processive readthrough. (E) Nrd1 and Nab3 recognize terminator sequences allowing the allosteric change in Pol II but depletion of Sen1 blocks removal of Pol II from the template.

## **Part 2: Mapping RBM16 to the Mammalian Transcriptome**

Paul Schaugency and Jeffry L. Corden

## ABSTRACT

The C-terminal Domain (CTD) of RNA Polymerase II (Pol II) is a major part of a regulatory network that links transcription to RNA processing. In *Saccharomyces cerevisiae*, Nrd1 is a transcriptional factor that binds to the CTD and nascent RNA and terminates transcription on a variety of specific RNAs. Nrd1 shares homology to the proteins RBM16 and SFRS15 in mammalian cells. Photoactivatable-Ribonucleoside-Enhanced Crosslinking and Immunoprecipitation (PAR-CLIP) has been used to define the RNAs that are bound to human RBM16. Of the PAR-CLIP products that were purified, non-coding RNAs (ncRNAs), mRNAs, and snoRNAs were the highly represented. This observation the possibility of a shared function between RBM16 and Nrd1.

## INTRODUCTION

RNA Polymerase II (Pol II) is responsible for the transcription of most protein coding genes and some ncRNAs in eukaryotes. The C-terminal domain (CTD) of Pol II is a scaffold to which many proteins bind during each of a transcription cycle (Buratowski, 2009). The CTD itself is modified to reflect the state of Pol II transcription (Chapman et al., 2007; Zhang and Corden, 1991). It is through the “CTD code” of phosphorylation states and other post-translational modifications that different factors and complexes can bind to influence transcription (Carroll et al., 2007; Nedeia et al., 2003).

In yeast, the Nrd1-Nab3-Sen1 (NNS) pathway is a complex of proteins involved in the attenuation of certain Pol II transcripts (Steinmetz et al., 2001). Nrd1 is a protein that interacts with CTD through its CTD interacting domain (CID) and the nascent RNA through its RNA recognition motif (RRM). These two domains define the function of this protein. Using homology and looking for a similar protein architecture two other related proteins were discovered in higher eukaryotes. These proteins were first referred to as SCAF4 and SCAF8, but now they are referred to as RBM16 and SFRS15 respectfully (Yuryev et al., 1996). Crystallization of the CID from these proteins seems to indicate that they interact with the CTD in a very similar manner (Lunde et al., 2010).

The NNS complex, in yeast, terminates the transcripts of snoRNAs, some mRNAs, and cryptic unstable transcripts (CUTs) (Arigo et al., 2006a; Arigo et al., 2006b; Steinmetz et al., 2001). Similar to yeast, snoRNA maturation requires the nuclear exosome (Berndt et al., 2012) Although an NNS-like pathway has never been found in higher eukaryotes, this similarity might suggest a mechanistic conservation. Unlike yeast,

C/D box snoRNAs in mammals are mostly found in the introns of genes (Hirose et al., 2003). This functional difference means that although there may be a similarity between Nrd1 and RBM16 on the protein level the mechanism of action would have to be different if RBM16 is involved in snoRNA maturation.

RBM16's function within the nucleus of mammalian cells is poorly understood. Using PAR-CLIP, we have pulled down and purified RNAs that are bound to RBM16. Definition of the RNAs purified, might give insight into the possible functions of this protein and how it compares to its yeast counterpart Nrd1. Further evidence of similarity between types of RNAs bound to both of these factors might translate to a similar mechanism of transcriptional regulation.

## RESULTS

Expression of 6xHis-TEV-Biotin tagged version of RBM16 was done using the Invitrogen flp-in Trex system. Correct expression of the tagged RBM16 was verified by western blot after treatment with doxycycline for 6, 12, 24, and 48 hours (Figure 17A). After 12 hours of doxycycline treatment, expression of RBM16-HTB was approximately equal to that of endogenous RBM16 levels (Figure 17A). For cross-linking experiments, 4-thiouridine and doxycycline were both added to the cell culture media and allowed to incubate with the cells for 12 hours.

A single cDNA library preparation was made from the RNA crosslinked to purified RBM16-HTB after treatment. A 6% polyacrylamide nucleic acid gel showed a plethora of PCR amplified cDNA from the purification (Figure 17B). Bioanalyzer results indicated that the final cDNA library was between 100-150 bps long (Figure 17C). Notice, that there was minor contamination by primer dimers even after the gel extraction.

Of the 32,923,767 sequences derived from sequencing the library, only 25,165,211 sequences had an identifiable 3' adaptor. After condensing the reads to remove duplicates 5,402,948 reads were left, of which 367,700 reads aligned to the hg19 genome only twice. This is only 6.8 % of the condensed reads and 1.1 % of the total reads before trimming.

Within those reads that did align, 273 genes were enriched within the dataset (Table 6). Of note are ncRNAs: Xist, NCRNA00164, and MALAT1 and several protein coding genes: HFM1, PDE3A, SLIT2, AUTS2, and SRRM2. Of those genes that had aligned reads, most had more reads at the 3' end of the gene than that 5' end of the gene

(Figure 18). 59 snoRNA loci were also enriched in this dataset (Table 2). Most of these snoRNAs were C/D box snoRNAs.

## DISCUSSION

Expression of a tagged version of RBM16 was the first step to purification and elucidation of target RNAs. The spliced gene for RBM16 is approximately 4kb in length. Using Invitrogen's Flp-in T<sub>REX</sub> expression system, we were able to incorporate a tetracycline/doxycycline inducible HTB tagged version of RBM16 into HEK-293 cells. The system uses Flp recombinase, Zeocin susceptibility, and hygromycin resistance to guarantee the protein is integrated into the genome. Further testing by western blot showed that, indeed, we could get reliable expression of our tagged RBM16 within 12 hours of treatment with doxycycline (Figure 17A).

Using a combination of PAR-CLIP and highly denaturing tandem affinity purification, we were able to purify RNAs that were specifically bound to RBM16. Even though the resulting library was sparse in terms of reads that aligned to the genome, we were able to identify some RNAs that RBM16 binds.

The largest amounts of reads aligned were of RBM16 binding to Xist (Table 6). Xist is a non-coding RNA involved in X chromosome inactivation (Maclary et al., 2013). Some other ncRNAs were found bound to RBM16 as well. Although the number of reads aligned to these ncRNAs were not as significant as Xist, this may point to a role for RBM16 in transcriptional control of ncRNAs. Although, Xist and MALAT1 seem to be pulled down in most human cell culture PAR-CLIP experiments (Friedersdorf and Keene, 2014). Other genes with high number of reads aligned were those of protein coding genes. Interestingly, of all genes that had at least 10 reads, more reads were found in the 3' end of the genes than the 5' end of the gene (Figure 18).

Of the 59 snoRNA genes that RBM16 binds, 51 are C/D box and 8 are H/ACA (Table 7). Most of these C/D box snoRNAs are contained within the introns of protein coding genes while H/ACA are processed in a different manner (Berndt et al., 2012; Hirose et al., 2003). Perhaps, RBM16 retains some function to regulate the maturation of snoRNAs. As the exosome is still conserved in the maturation of snoRNAs, RBM16 may act to bridge these two processes. This mechanism, however, would not be through transcriptional termination, but an alternative unknown mechanism most likely involving the splicing machinery.

This dataset hints at the function of RBM16 within the mammalian nucleus. In yeast, Nrd1 binds and recruits the nuclear exosome and is required for proper snoRNA maturation (Grzechnik and Kufel, 2008; Kim et al., 2006; Vasiljeva and Buratowski, 2006). It does seem through the pulldown of C/D box snoRNAs RBM16 retains some function in the maturation of snoRNA from its yeast homolog Nrd1. Nrd1 is also important in controlling pervasive transcription of non-coding RNAs and some mRNAs (Arigo et al., 2006a; Arigo et al., 2006b; Creamer, 2011; Thiebaut et al., 2006). It is possible that RBM16 is also part of some complex regulating ncRNAs protein coding genes, again, through linkage to the nuclear exosome. Although RBM16's mechanism of action could be quite different from that of Nrd1, their final outcome for transcriptional control of some RNAs might be similar. This foundation may lead to further evidence of these assumptions.

## **MATERIALS AND METHODS**

### **Expression of RBM16-HTB in HEK-293 cells**

Knocking in of the HTB tagged version of RBM16 was done using the Invitrogen Flp-In TRex system per the manufacturers instructions. Cells that were hygromycin resistant were tested by treating with 1ug/ml doxycycline for up to 48 hours and measuring protein levels using a western blot as previously described (Figure 17A) (Creamer, 2011).

### **Purification of RBM16-HTB**

HEK-293 cells that expressed RBM16-HTB after doxycycline treatment were grown to approximately 90% confluency in 10 100mm cell culture dishes. Cells were treated with 1ug/ml doxycycline and 4-thiouridine for 12 hours. After treatment, the cells were irradiated using a mercury arc-lamp at 365nm for 10s. Further steps taken during purification were identical to what has been described previously (Creamer, 2011).

### **Library Preparation**

Libraries were made as previously described (Creamer, 2011). Resulting sequences were also analyzed as previously described (Schaughency, 2014), but with the following difference: the sequences were aligned using the hg19 genome.

**Figure 17. Expression and purification of RBM16-HTB**

A. Western blot of whole cell extracts made from cells treated with doxycycline for the indicated times. Top western was probed with an anti-RBM16 antibody and the bottom western was probed with an anti-RGS6XHIS antibody. B. 6% polyacrylamide gel of the cDNA library after PCR amplification. C. Visual representation of a Bioanalyzer lane containing the gel purified fragment of the cDNA library.

**Figure 18. Reads that map to the 5' or 3' end of each gene**

Pie-chart of the number of reads that were at the 3' end of a given gene (black) vs the 5' end (grey).

**Table 6. Genes with RBM16 reads aligned**

List of all genes containing more than 100 reads aligned in order from highest to lowest.

### **Part 3: Analyses of Nrd1-Nab3-Sen1 Termination Pathway PAR-CLIP Data Sets**

Paul Schaugency and Jeffry L. Corden

## INTRODUCTION

Loosely conserved regions at the 3' end of yeast genes contain signals for transcriptional termination. These termination regions (or terminators) bind proteins that are part of complexes associated with the elongating RNA Polymerase II. In protein-coding genes, the CF1 complex binds to these terminators leading to assembly of the cleavage and polyadenylation machinery (Kloetgen et al., 2014). Alternatively, Nrd1 and Nab3 recognize elements downstream of snoRNAs and cryptic unstable transcripts (CUTs) (Carroll et al., 2007; Carroll et al., 2004; Creamer, 2011; Steinmetz et al., 2001; Steinmetz et al., 2006; Wlotzka et al., 2011) and this leads to the association of a complex that contains the DNA/RNA helicase Sen1 (Vasiljeva et al., 2008). Neither of these mechanisms of termination has yet to be elucidated.

Methods of studying protein-nucleic acid interactions have relied heavily on crosslinking. Chromatin immunoprecipitation (ChIP) is commonly used to study DNA-protein interactions (Barski et al., 2007). The method uses the reversible crosslinking reagent formaldehyde to purify protein-nucleic acid complexes. For RNA-protein interactions, formaldehyde crosslinking leads to high background, because of the non-specific nature of the chemical reaction. Crosslinking and immunoprecipitation (CLIP) uses UV-B to successfully and specifically crosslink protein-RNA complexes. Marrying the now inexpensive high throughput sequencing to the CLIP method (HITS-CLIP) allows for insights into the functions of many different RNA binding proteins (Darnell, 2010).

To study the Nrd1-Nab3-Sen1 (NNS) termination pathway in yeast, we have relied on the Photoactivatable Ribonucleoside enhanced Crosslinking and Immunoprecipitation (PAR-CLIP) method (Hafner et al., 2010). This has allowed us to further understand the relationship between RNA polymerase II (Pol II) and the non-poly(A) mediated termination pathway. PAR-CLIP has been used to map all binding sites of all three factors across the genome and visualize Pol II readthrough after Nrd1, Sen1, and Ysh1 mutation (Creamer, 2011; Jamonnak, 2011) .

Like HITS-CLIP, PAR-CLIP is a method to specifically crosslink RNA Binding Proteins to the RNA (Hafner et al., 2010). It does this through irradiation with 365nm UV to a culture of cells that have been treated with 4-thiouracil (4TU) or 4-thiouridine (4SU). In yeast, 4TU is easily taken up, converted to UTP and incorporated into total RNA. In mammalian cell culture, 4SU is used because of a lack of the correct uracil phosphoribosyltransferase (UPRT) to take it up 4TU from the media (Melvin et al., 1978; Miller et al., 2009). After incorporation, cells are irradiated with 365nm UV to crosslink the thio-residues that have now been included in a vast number of transcripts within the transcriptome. This wavelength of UV does not crosslink regular RNA-protein complexes. This reduces the background seen in CLIP or HITS-CLIP protocols.

Unlike formaldehyde, the thio crosslink is irreversible and causes trouble for the reverse transcriptase. During the reverse transcriptase reaction, the 4TU or 4SU will cause a T to C transition in the resulting cDNA (Hafner et al., 2010). Although, harder to deal with in the analyses of these sequences, this provides a map of potential binding sites on all of the RNAs that were purified in this method.

After sequencing, PAR-CLIP has a few computational challenges that have to be overcome: Normalization of the reads from different sequencing runs and library preparations, visual representation of the sequences after mapping, and incorporating T to C transitions into the analysis. We have developed bioinformatic pipelines that try to deal with these challenges and lay a general framework for analyses of PAR-CLIP datasets in the future.

## METHODS

The first pipeline is used to describe the binding of Nrd1, Nab3, and Sen1 within the transcriptome. The second pipeline was used to describe the position of Pol II after mutation of Nrd1, Sen1, or Ysh1. The third pipeline was used to describe the binding of RBM16 (a Nrd1 homolog) to RNAs in HEK-293 cells. The steps used in each pipeline are described below.

Pipeline 1 (Figure 19) : Nrd1, Nab3 , Sen1-HTB tagged datasets (Creamer, 2011; Jamonnak, 2011)

### 1. Program: removelinkers.R

Author: Sarah Wheelan

Overview:

This program reads a fasta or fastq file and implements a dynamic matching algorithm to locate the adaptors/linkers and split them from the rest of the sequence.

Usage:

```
removelinkers.R -i input_file -o output_file_prefix -q fastq (default: T) -l1  
left_linker_outer -l2 left_linker_inner -r1 right_linker_outer -r2 right_linker_inner  
-quart quartile, from 1-4 -int print_intermediates -el1 error_rate_start_l1  
(default:0.1) -el2 error_rate_start_l2 (default:0.1) -er1 error_rate_start_r1  
(default:0.1) -er2 error_rate_start_r2 (default:0.1)
```

linker schema (XX is non-adaptor sequence):

l1l1l1l1l1-l2l2l2l2l2-XXXXXXXXXXXXXXXXXX-r2r2r2r2r2-r1r1r1r1r1

Note: If there is only one right or left linker, choose either the inner or outer as they are equivalent

Where:

input\_file : fasta or fastq sequence file

output\_file : prefix for the files of trimmed sequences

fastq : T=fastq file, F=fasta file

left\_linker\_outer : 5'-most linker

left\_liner\_inner : second 5' linker inside outer linker

right\_linker\_outer : 3'-most linker

right\_linker\_inner : second 3' linker inside outer linker

quartile : which quartile of the file to work on, to break up big files; no entry means do the whole file

print\_intermediates : should all intermediate trimmed reads be saved in separate files, or only the end product? (default = T)

error\_rate\_start\_l1 : starting value for the dynamic error rate for l1 linker  
(default = 0.1)

error\_rate\_start\_l2 : starting value for the dynamic error rate for l2 linker  
(default = 0.1)

error\_rate\_start\_r1 : starting value for the dynamic error rate for r1 linker  
(default = 0.1)

error\_rate\_start\_r2 : starting value for the dynamic error rate for r2 linker  
(default = 0.1)

Example:

```
removelinkers.R -i sequences.fastq -o trimmedsequences_1_ -r2
```

```
XXXXXXXXXXXXXXXX(3' adaptor sequence) -quart 1
```

## 2. Program: rmshortseqraw13.pl

Author: Paul Schaughency

Overview:

This program reads a raw sequence file and prints out only those sequences that are longer than 13 nucleotides long.

Usage:

```
rmshortseqraw13.pl -i input_file -o output_file
```

Example:

```
rmshortseqraw13.pl -i sequences.raw -o sequences>13.raw
```

## 3. Program: Bowtie

Author: (Langmead et al., 2009)

Overview:

A short read alignment program that uses the Burrows-Wheeler transform to efficiently map short reads to any genome.

Usage:

See (Langmead et al., 2009)

Example:

For 4a,b,c: bowtie -v 1 SacCer2 -m 1 -sam—nohead

For 4d: bowtie -v1 SacCer2 -m 1

#### 4a. Program: SCfixwig.pl

Authors: Paul Schaugency, Tyler Creamer

Overview: Takes a sam output file from bowtie and converts it into a wig file used by visualization programs. It does not multiply reads to normalize them. Instead it counts 1 read as 1 read.

Usage:

SCfixwig.pl -i input sam file -p output plus wig file name -m output minus wig file name

Example:

SCfixwig.pl -i alignedsequences.sam -p treatmentplusstrand.wig -m treatmentminusstrand.wig

#### 4b. Program: SCfixwigwithmulti.pl

Authors: Paul Schaugency, Tyler Creamer

Overview: Takes a sam output file from bowtie and converts it into a wig file used by visualization programs. It normalizes all reads to  $10^7$  reads by calculating

first a multiplier to apply to all reads then counting each read as a fraction of that multiplier. The multiplier is defined as the number of reads aligned/ $10^7$ .

Usage:

SCfixwigwithmulti.pl -i input sam file -p output plus wig file name -m output minus wig file name

Example:

SCfixwigwithmulti.pl -i alignedsequences.sam -p treatmentplusstrand\_norm.wig -m treatmentminusstrand\_norm.wig

#### 4c. Program: extractsamSC.pl

Author: Paul Schaughency

Overview: Splits a samfile into two files: one for the plus strand reads and one for the minus strand reads. Keeps the sam format for both files.

Usage:

extractsamSC.pl < Any Sam File

Example:

extractsamSC.pl < Alignedreads.sam

#### 4d. Program: SCT2C.pl

Author: Paul Schaughency

Overview: Takes a raw bowtie output file and converts it into a wig file used by visualization programs. This program only counts T to C transitions.

Usage:

```
SCT2C.pl -i rawbowtie file -p output plus wig file name -m output minus wig file name
```

Example:

```
SCT2C.pl -i alignedsequences.rawbowtie -p treatmentplusstrand_T2C.wig -m treatmentminusstrand_T2C.wig
```

## 5. Program: binmappingv8.pl

Author: Paul Schaugency

Overview: Using a known annotation file and a two samfiles of plus and minus strand reads, can bin reads into any number of bins to figure out the distribution of reads within a given annotation.

Usage:

```
binmappingv8.pl [Gene Sorting Options] -g Custom Gene List -p input sam file -m input sam file -o output name
```

[Gene Sorting Options]

-h sort and check for overlap in genes that have high transcription (txn > or = 6)

-d sort and check for overlap in genes that have mid range transcription (txn < 6 > 3.3)

-l sort and check for overlap in genes that have low transcription (txn < or = 3.3)

-a sort and check for overlap in all genes

-c sort and check for overlap in a custom gene list (if this is defined you must also define -g)

[Input Files]

-g Custom Gene List

Note: Must be a text file the following format:

Gene\_Name <tab> Chromosome <tab> Gene Start <tab> Gene End

-p Sorted Plus Strand Sam File

-m Sorted Minus Strand Sam File

-o Base Name for all Output File

Example:

```
binmappingv8.pl -c -g geneannotation.txt -p plusstrandalignments.sam -m  
minusstrandalignments.sam -o output.txt
```

Pipeline 2 (Figure 20) : Nrd1 Anchor Away, Rpb2-HTB datasets (Schaughency, 2014)

1&2. See Pipeline 1

3. Program: `collapserawreads.pl`

Author: Paul Schaughency

Overview: Takes a raw bowtie output file and collapses all reads that are exactly the same into only one read.

Usage:

```
collapserawreads.pl -i input_file -o output_file
```

Example:

```
collapserawreads.pl -i rawsequences.raw -o collapsedrawsequences.raw
```

4. Program: Bowtie

Note: See pipeline 1 step 3

Example:

```
For 5a,b: bowtie -v 2 SacCer3tRNA -m 1 -sam—nohead -best -strata -y
```

```
For 5c: bowtie -v 2 SacCer3tRNA -m 1 -best -strata -y
```

5. Program: `AlignedMinusExtract.pl`

Overview: Converts the unread reads from bowtie and puts them back into a format so they can be used again to align to the genome.

Usage:

```
AlignedMinusExtract.pl -i input_file -o output_file
```

Example:

```
AlignedMinusExtract.pl -i tRNAUnmappedreads.raw -o  
tRNAUnmappedfinal.raw
```

## 6. Program: Bowtie

Note: See pipeline 1 step 3

Example:

For 5a,b: `bowtie -v 2 SacCer3 -m 1 -sam—nohead -best -strata -y`

For 5c: `bowtie -v 2 SacCer3 -m 1 -best -strata -y`

## 7a. Program: SCFullReadWigNoMulti.pl

Authors: Paul Schaughency

Overview: Takes a sam output file from bowtie and converts it into a wig file used by visualization programs. It does not multiply reads to normalize them. Instead it counts 1 read as 1 read. Every point across the entire read is counted.

Usage:

SCFullReadWigNoMulti.pl -i input sam file -p output plus wig file name -m  
output minus wig file name

Example:

SCFullReadWigNoMulti.pl -i alignedsequences.sam -p treatmentplusstrand.wig -  
m treatmentminusstrand.wig

#### 7b. Program: SCFullReadWigWithMulti.pl

Authors: Paul Schaugency

Overview: Takes a sam output file from bowtie and converts it into a wig file  
used by visualization programs. It normalizes all reads to  $10^7$  reads by  
calculating first a multiplier to apply to all reads then counting each read as a  
fraction of that multiplier. Every point across the entire read is counted.

Usage:

SCFullReadWigWithMulti.pl -i input sam file -p output plus wig file name -m  
output minus wig file name

Example:

SCFullReadWigWithMulti.pl -i alignedsequences.sam -p  
treatmentplusstrand\_norm.wig -m treatmentminusstrand\_norm.wig

#### 7c. Program: SCT2CV2.pl

Author: Paul Schaugency

Overview: Takes a raw bowtie output file and converts it into a wig file used by visualization programs. This program only counts T to C transitions and counts multiple T to C transitions in one read as separate entities

Usage:

SCT2CV2.pl -i rawbowtie file -p output plus wig file name -m output minus wig file name

Example:

SCT2CV2.pl -i alignedsequences.rawbowtie -p treatmentplusstrand\_T2C.wig -m treatmentminusstrand\_T2C.wig

8. Program: wig2bedv2.pl

Author: Paul Schaughency

Overview: Converts wig file format to bed file format.

Usage: wig2bedv2.pl -i input\_file -o output\_file

Example: wig2bedv2.pl -i alignedsequences.wig -o alignedsequences.bed

9. Program: globalreadthroughv3.pl

Author: Paul Schaughency

Overview: Calculates the global readthrough percentage for each base in the entire genome. Outputs percentage wig and bed files.

Usage: globalreadthroughv3.pl -a input bed file 1 -b input bed file 2 -c input bed file 3 -d input bed file 4 -x nucleotides upstream -y nucleotides downstream -z read cutoff

Example: Usage: globalreadthroughv3.pl -a plusstrandcontrol.bed -b minusstrandcontrol.bed -c plusstrandtreatment.bed -d minusstrandtreatment.bed -x 500 -y 500 -z 1000

### Pipeline 3 (Figure 21) : RBM16-HTB Dataset

1-3. See Pipeline 2

4. Program: Bowtie

Note: See pipeline 1 step 3

Example:

For 5a: bowtie -v 2 hg19tRNAs -m 1 -sam—nohead -best -strata -y

For 5b: bowtie -v 2 hg19tRNAs -m 1 -best -strata -y

5. Program: AlignedMinusExtract.pl

Note: See pipeline 2 step 5

6. Program: Bowtie

Note: See pipeline 1 step 3

Example:

For 5a: bowtie -v 2 hg19 -m 1 -sam—nohead -best -strata -y

For 5b: bowtie -v 2 hg19 -m 1 -best -strata -y

#### 7a. Program: HGFullReadWig.pl

Authors: Paul Schaughency

Overview: Takes a sam output file from bowtie and converts it into a wig file used by visualization programs. It does not multiply reads to normalize them. Instead it counts 1 read as 1 read. Every point across the entire read is counted.

Usage:

HGFullReadWig.pl -i input sam file -p output plus wig file name -m output minus wig file name

Example:

HGFullReadWig.pl -i alignedsequences.sam -p treatmentplusstrand.wig -m treatmentminusstrand.wig

#### 7b. Program: HGT2CV2.pl

Author: Paul Schaughency

Overview: Takes a raw bowtie output file and converts it into a wig file used by visualization programs. This program only counts T to C transitions and counts multiple T to C transitions in one read as separate entities

Usage:

HGT2CV2.pl -i rawbowtie file -p output plus wig file name -m output minus wig  
file name

Example:

HGT2CV2.pl -i alignedsequences.rawbowtie -p treatmentplusstrand\_T2C.wig -m  
treatmentminusstrand\_T2C.wig

## DISCUSSION

The goal with any analyses like these is to try to accurately map all RNAs bound to these RNA binding factors. As described previously, PAR-CLIP was used to make cDNA libraries from factors tagged for highly denaturing tandem purification. The results of the sequencing of these libraries were large files containing millions of reads all 32bp – 50 bp long.

The first step in analyzing any library is to try to remove any sequences pertaining to the 3' adaptor. When libraries are made, adaptors are ligated at the 5' and 3' end of the RNA of interest. These adaptors allow for the reverse transcription, PCR amplification, and sequencing of these RNAs. The Illumina sequencing primer ends at the end of the end of the 5' adaptor. Therefore, none of the 5' adaptor should be present in the final sequencing reads. The 3' adaptor, although, will be present because we size selected for small insert sizes.

There are many ways to go about trimming the 3' adaptor from the sequencing reads. The most basic idea is to search for any part of the 3' adaptor and to eliminate it from the sequences. This is quite effective, but because the accuracy of the Illumina machine to incorporate the correct base decreases from 5' to 3', many reads may be thrown out accidentally. An open-source R package called Bioconductor (Gentleman et al., 2004) has been developed and contains a slightly better algorithm for 3' adaptor removal. In brief, it uses a heuristic to allow for mismatches closer to the 3' end of the read. Dr. Sarah Wheelan wrote an easy to use interface for this program, which we used in all for all of our datasets.

After trimming the sequences, depending on the amount of sequences that are trimmed, the reads can be condensed. Condensing the reads is defined as counting all exact duplicate reads as only one read. There are two reasons that reads could be the same. First, they were amplified from the same cDNA or, alternatively, they came from two different RNAs crosslinked in the same manner. Although, the latter is certainly possible, the former is a bigger concern. The presence of the T to C transitions caused by the incorporation of 4tU as well as the RNase T1 step of the library preparation point toward there being exact duplicate reads more from PCR amplification bias.

Bowtie is an efficient short read alignment program (Langmead et al., 2009). In the first experiments with PAR-CLIP, bowtie was used to conservatively align the reads to the current yeast genome (SacCer2). These reads were allowed only one mismatched base and only one unique alignment. In subsequent experiments, the reads were allowed to contain two mismatched bases and one non-unique alignment. The main difference between the first PAR-CLIP experiments and the subsequent ones was the change from 32bp reads to 50 bp reads. Allowing for only one mismatched base was deemed too conservative because of the amount of T to C transitions that could be sequenced with a longer read. This required a rewrite of all downstream programs in order to compensate for the extra information. The switch from one unique alignment to one non-unique alignment was done to try and alleviate the concern that some reads were being discarded because they were too repetitive. It is unclear whether switching from unique to non-unique would be helpful for future datasets.

Starting with the anchor away data sets, reads that mapped to tRNAs were removed from every dataset by running bowtie against a pseudogenome of all tRNAs in

yeast (or human) and then taking those reads that do not align and using those for subsequent analyses (AlignedMinusExtract.pl). Even with highly denaturing tandem affinity purification, we have seen reads map to tRNAs in every dataset (data not shown). Whether or not this is significant has yet to be determined, but for the data sets in question this was considered background.

After alignment, all datasets need to be normalized for any usable computational algorithm (SCfixwig.pl, SCfixwigwithmulti.pl, etc.) . For this, the simplest method of normalization was chosen; to adjust all read counts to that of the total reads aligned per  $10^7$  reads. This generally puts all reads within the same range on a per experiment basis. One caveat is that the number of mapped reads number within an experiment should be generally close to begin with or else the algorithm tends to over estimate certain data sets over others. All of our datasets within all experiments were close enough together for this to work. Other normalization techniques, as described before, could work to alleviate this problem, but, because some depend on assumptions that changes to transcription do not happen to a vast majority of transcripts, these would not necessarily be better.

The datasets, also, needed to be converted to a format so that they could be analyzed visually as well as computationally. The file formats used was .wig and .bed. Both file formats are fairly similar with major difference being that in a .wig file the chromosome header contains the chromosome number for all data points after that header while the .bed format contains the chromosome number in each line. The only other minor difference is that the .bed file format has a column dedicated to strandedness (plus or minus strand) while the .wig file format does not. This requires .wig to have a separate file for plus (Watson) strand reads and minus (Crick) strand reads. Since the

normalization happens during conversion to a wig file, sometimes the wig files had to be converted back to .bed file for computational reasons.

In the first set of PAR-CLIP experiments, the subsequent wig files were made using the midpoint of the read rounded down. If all reads were treated this way, then it should give an accurate map of approximately where the reads were crosslinked. A more accurate, but less robust way of finding crosslink sites was to only map T to C transitions. The downside of this, although it was able to get us binding motifs, was that there were much less reads to work with when you confine it to just T to C transitions. In subsequent analyses of PAR-CLIP experiments, we opted to represent every bp of the reads that mapped. This was important in order to accurately map readthrough of Pol II.

It is from here that the analyses of the individual experiments differ in terms of computational output. Most likely, programs used in a particular dataset will not be applicable to most PAR-CLIP datasets. It is worth noting, however, that the ideas behind these programs might still be usable in a different context.

Of note from the first pipeline, are the division of genes into bins and the counting of reads into the plus and minus strand of each bin. This was done by dividing a gene into a number of user defined segments, then, annotating an array of numbers each representing 1bp on each chromosome to define each bin. This came with the caveat that no two genes could overlap in the same direction or within the 5' or 3' UTR region defined by the user. This was not a problem for the gene annotation dataset used for this project because gene overlap was rare. For larger custom gene annotation lists this could eliminate too many genes from the analysis. Once all genes had defined bins all reads

were then counted that fell within each bin for each gene. Averaging these gene bins, then, was a simple computational task.

Within the anchor away dataset analysis, the calculation of percentage readthrough was unique. Similar to calculating a traveling ratio, percentage readthrough takes the difference of the percent of reads downstream of a point within the genome. This difference comes from percentages calculated from the treatment versus the control datasets. When calculated for every base in the yeast genome, it illuminates potential readthrough sites for the Nrd1 anchor away dataset. The Nrd1 anchor away dataset, though, is unique in that the readthrough is pretty long. The percentage readthrough calculation has trouble with datasets with shorter readthroughs (Sen1, Ysh1). Optimization of the calculation of percentage readthrough could alleviate this problem. Despite this caveat, the percentage readthrough calculation was able to accurately predict termination regions when the readthrough extended sufficiently downstream (Nrd1).

PAR-CLIP is a powerful method that can elucidate many unique and interesting interactions between RNA and protein within the cell. We have successfully used this method to describe the interactions of the Nrd1-Nab3-Sen1 termination pathway and RNA Pol II. We have had to develop many different bioinformatic pipelines in order to analyze the subsequent datasets. Taken together these pipelines can act as guidance for analysis of future PAR-CLIP datasets.

### **Figure 19. Nrd1, Nab3, Sen1 –HTB pipeline**

A schematic diagram of the bioinformatic pipeline used to analyze libraries made from purifying Nrd1, Nab3, Sen1 – HTB in yeast. Where there is an arrow, the output of the previous step becomes the input of the subsequent step.

**Laboratory Experience:**

Thesis research	2009-2014	Lab of Dr. Jeffry Corden	Johns Hopkins SoM
-----------------	-----------	--------------------------	-------------------

Identified novel termination points for the Nrd1-Nab3 termination pathway genome wide using PAR-CLIP. This involved rapid conditional depletion of different termination factors from the nucleus using rapamycin followed by specific crosslinking to 4-thiouracil containing RNA bound to proteins. Sequencing was done on the purified RNA and specific bioinformatic pipelines to analyze the data were made.

Research Rotation	2008-2009	Lab of Dr. John Lorsch	Johns Hopkins SoM
-------------------	-----------	------------------------	-------------------

Examined the effects of the yeast consensus sequence on translation *in vivo* and *in vitro*

Research Rotation	2008-2009	Lab of Dr. Geraldine Seydoux	Johns Hopkins SoM
-------------------	-----------	------------------------------	-------------------

Examined whether or not expression of 3'UTR GFP fusions in *c. elegans* males are viable.

CRTA Fellow	2006-2008	Lab of Dr. Howard Young	NCI-Frederick
-------------	-----------	-------------------------	---------------

Investigated IL-15 control of bid expression in primary human natural killer cells.

Summer Internship	2005	Lab of Dr. Paul Smith	UMBC
-------------------	------	-----------------------	------

Worked on synthesizing a novel naphthanol analog of UK-1 as potential Topoisomerase and HIV-1 Integrase inhibitor.

Senior Project	2004-2006	Lab of Dr. Edward Orlando	St. Mary's College
----------------	-----------	---------------------------	--------------------

Worked on treating the hermaphroditic *Rivulus marmoratus* with ethinyl estradol to try to direct the development of true females.

## **Service and Leadership:**

**Student Mentor**, Johns Hopkins School of Medicine. 2008-Present

Assisted Dr. Jeffry Corden with the supervision of an undergraduate student, a graduate rotation student, a technician, and an individual looking for some wet lab experience. Taught correct laboratory safety and techniques, and helped their professional development.

**Biochemistry Lab Assistant**, St. Mary's College of Maryland. 2005-2006

Worked with Dr. P. Mertz to prepare various solutions and gels for use in an undergraduate biochemistry laboratory. Oversaw and assisted with many biochemistry lab classes.
